## 1 Introduction

So far we have studied regression models. That is, models for the conditional expectation of one variable given the values of other variables, or linear approximations to those expectations. Now we wish to study relations between random variables that are not regressions. We have already seen some examples: the relationship between $y_{t}$ and $y_{t-1}$ in an $\operatorname{ARMA}(1,1)$ model, or the geometric distributed lag model.

A linear regression model can be seen as a linear relationship between observable and unobservable variables with the property that the regressors are orthogonal to the unobservable term. For example, given two variables $\left(y_{i}, x_{i}\right)$, the regression of $y$ on $x$ is

$$
\begin{equation*}
y_{i}=\alpha+\beta x_{i}+u_{i} \tag{1}
\end{equation*}
$$

where $\beta=\operatorname{Cov}\left(y_{i}, x_{i}\right) / \operatorname{Var}\left(x_{i}\right)$, therefore $\operatorname{Cov}\left(x_{i}, u_{i}\right)=0$.
Similarly, the regression of $x$ on $y$ is:

$$
x_{i}=\gamma+\delta y_{i}+\varepsilon_{i}
$$

where $\delta=\operatorname{Cov}\left(y_{i}, x_{i}\right) / \operatorname{Var}\left(y_{i}\right)$, and $\operatorname{Cov}\left(y_{i}, \varepsilon_{i}\right)=0$. Solving the latter for $y_{i}$ we can also write:

$$
\begin{equation*}
y_{i}=\alpha^{\dagger}+\beta^{\dagger} x_{i}+u_{i}^{\dagger} \tag{2}
\end{equation*}
$$

with $\alpha^{\dagger}=-\gamma / \delta, \beta^{\dagger}=1 / \delta, u_{i}^{\dagger}=-\varepsilon_{i} / \delta$.
Both (1) and (2) are statistical linear relationships between $y$ and $x$. If we are interested in some economic relation between $y$ and $x$, how should we choose between (1) and (2) or none of the two? If the goal is to describe means, clearly we would opt for (1) if interested in the mean of $y$ for given values of $x$, and we would opt for (2) if interested in the mean of $x$ for given values of $y$.

In equation (2) $\operatorname{Cov}\left(x, u^{\dagger}\right) \neq 0$ but $\operatorname{Cov}\left(y, u^{\dagger}\right)=0$ whereas in equation (1) the opposite is true. However, in the ARMA(1,1) model (referred to in the time series class notes) both the left-hand side and the right-hand side variables are correlated with the error term.

To respond a question of this kind we need a prior idea about the nature of the unobservables in the relationship. We first illustrate this situation by considering measurement error models.

## 2 Measurement error

Consider an exact relationship between the variables $y_{i}^{*}$ and $x_{i}^{*}$ :

$$
y_{i}^{*}=\alpha+\beta x_{i}^{*}
$$

Suppose that we observe $x_{i}^{*}$ without error but we observe an error-ridden measure of $y_{i}^{*}$ :

$$
y_{i}=y_{i}^{*}+v_{i}
$$

where $v_{i}$ is a zero-mean measurement error independent of $x_{i}^{*}$. Therefore,

$$
y_{i}=\alpha+\beta x_{i}^{*}+v_{i} .
$$

In this case $\beta$ coincides with the slope coefficient in the regression of $y_{i}$ on $x_{i}^{*}$ :

$$
\beta=\frac{\operatorname{Cov}\left(x_{i}^{*}, y_{i}\right)}{\operatorname{Var}\left(x_{i}^{*}\right)}
$$

Now suppose that we observe $y_{i}^{*}$ without error but $x_{i}^{*}$ is measured with an error $\varepsilon_{i}$ independent of $\left(y_{i}^{*}, x_{i}^{*}\right)$ :

$$
x_{i}=x_{i}^{*}+\varepsilon_{i} .
$$

The relation between the observed variables is

$$
\begin{equation*}
y_{i}^{*}=\alpha+\beta x_{i}+\zeta_{i} \tag{3}
\end{equation*}
$$

where $\zeta_{i}=-\beta \varepsilon_{i}$. In this case the error is independent of $y_{i}^{*}$ but is correlated with $x_{i}$. Thus, $\beta$ coincides with the inverse slope coefficient in the regression of $x_{i}$ on $y_{i}^{*}$ :

$$
\begin{equation*}
\beta=\frac{\operatorname{Var}\left(y_{i}^{*}\right)}{\operatorname{Cov}\left(x_{i}, y_{i}^{*}\right)} . \tag{4}
\end{equation*}
$$

In general, inverse regression may make sense if one suspects that the error term in the relationship between $y$ and $x$ is essentially driven by measurement error in $x$. As it will become clear later (4) can be interpreted as an instrumental-variable parameter in the sense that $y_{i}^{*}$ is used as an instrument for $x_{i}$ in (3). Next, we consider measurement error in regression models as opposed to exact relationships.

### 2.1 Regression model with measurement error

Measurement error may be the result of conceptual differences between the variable of economic interest and the one available in data, but it could also be the result of rounding errors or misreporting in survey data or administrative records.

Let us consider the regression model

$$
y_{i}^{*}=\alpha+\beta x_{i}^{*}+u_{i}^{*}
$$

where $u_{i}^{*}$ is independent of $x_{i}^{*}$. Below we distinguish two cases: one in wish there is only measurement error in $y_{i}^{*}$ and another in which there is only measurement error in $x_{i}^{*}$.

Measurement error in $y_{i}^{*}$ We observe $y_{i}=y_{i}^{*}+v_{i}$ such that $v_{i} \perp\left(x_{i}^{*}, u_{i}^{*}\right)$. In this case,

$$
y_{i}=\alpha+\beta x_{i}^{*}+\left(u_{i}^{*}+v_{i}\right),
$$

so that

$$
\beta=\frac{\operatorname{Cov}\left(x_{i}^{*}, y_{i}^{*}\right)}{\operatorname{Var}\left(x_{i}^{*}\right)}=\frac{\operatorname{Cov}\left(x_{i}^{*}, y_{i}\right)}{\operatorname{Var}\left(x_{i}^{*}\right)} .
$$

The only difference with the original regression model is that the variance of the error term is larger due to the measurement error component, which means that the $R^{2}$ will be smaller:

$$
R_{*}^{2}=\frac{\beta^{2} \operatorname{Var}\left(x_{i}^{*}\right)}{\beta^{2} \operatorname{Var}\left(x_{i}^{*}\right)+\sigma_{u}^{2}}, \quad R^{2}=\frac{\beta^{2} \operatorname{Var}\left(x_{i}^{*}\right)}{\beta^{2} \operatorname{Var}\left(x_{i}^{*}\right)+\sigma_{u}^{2}+\sigma_{v}^{2}},
$$

so that the larger $\sigma_{v}^{2}$ the smaller $R^{2}$ will be relative to $R_{*}^{2}$ :

$$
R^{2}=\frac{R_{*}^{2}}{1+\frac{\sigma_{v}^{2}}{\beta^{2} \operatorname{Var}\left(x_{i}^{*}\right)+\sigma_{u}^{2}}}
$$

Measurement error in $x_{i}^{*}$ Now $x_{i}=x_{i}^{*}+\varepsilon_{i}$ such that $\varepsilon_{i} \perp\left(x_{i}^{*}, u_{i}^{*}\right)$. In this case,

$$
y_{i}^{*}=\alpha+\beta x_{i}+\left(u_{i}^{*}-\beta \varepsilon_{i}\right) .
$$

Then

$$
\beta=\frac{\operatorname{Cov}\left(x_{i}, y_{i}^{*}\right)}{\operatorname{Var}\left(x_{i}\right)}=\frac{\operatorname{Cov}\left(x_{i}^{*}, y_{i}^{*}\right)}{\operatorname{Var}\left(x_{i}^{*}\right)+\sigma_{\varepsilon}^{2}}=\frac{\beta}{1+\frac{\sigma_{\varepsilon}^{2}}{\operatorname{Var}\left(x_{i}^{*}\right)}}=\beta-\beta\left(\frac{\lambda}{1+\lambda}\right)
$$

where $\lambda=\sigma_{\varepsilon}^{2} / \operatorname{Var}\left(x_{i}^{*}\right)$. Thus, OLS estimates will be biased for $\beta$ with a bias that depends on the noise to signal ratio $\lambda$. For example, if $\lambda=1$ the regression coefficient will be half the size of the effect of interest.

An example: $y_{i}^{*}=$ consumption, $x_{i}^{*}=$ permanent income, $u_{i}^{*}=$ transitory consumption, $\varepsilon_{i}=$ transitory income.

Identification using $\lambda$ If we have measurements of $\lambda$ or $\sigma_{\varepsilon}^{2}$ then consistent estimation may be based on the following expressions:

$$
\begin{equation*}
\beta=(1+\lambda) \frac{\operatorname{Cov}\left(x_{i}, y_{i}^{*}\right)}{\operatorname{Var}\left(x_{i}\right)}=\frac{\operatorname{Cov}\left(x_{i}, y_{i}^{*}\right)}{\operatorname{Var}\left(x_{i}\right)-\sigma_{\varepsilon}^{2}} . \tag{5}
\end{equation*}
$$

More generally, if $x_{i}$ is a vector of variables measured with error, so that

$$
\begin{aligned}
& y_{i}=x_{i}^{\prime} \beta+\left(u_{i}-\varepsilon_{i}^{\prime} \beta\right) \\
& x_{i}=x_{i}^{*}+\varepsilon_{i}, \quad E\left(\varepsilon_{i} \varepsilon_{i}^{\prime}\right)=\Omega,
\end{aligned}
$$

a vector-valued generalization of (5) takes the form:

$$
\beta=\left[E\left(x_{i} x_{i}^{\prime}\right)-\Omega\right]^{-1} E\left(x_{i} y_{i}\right) .
$$

## 3 Instrumental-variable model

### 3.1 Identification

The set-up is as follows. We observe $\left\{y_{i}, x_{i}, z_{i}\right\}_{i=1}^{n}$ with $\operatorname{dim}\left(x_{i}\right)=k$, $\operatorname{dim}\left(z_{i}\right)=r$ such that

$$
y_{i}=x_{i}^{\prime} \beta+u_{i} \quad E\left(z_{i} u_{i}\right)=0
$$

Typically there will be overlap between variables contained in $x_{i}$ and $z_{i}$, for example a constant term ("control" variables). Variables in $x_{i}$ that are absent from $z_{i}$ are endogenous explanatory variables. Variables in $z_{i}$ that are absent from $x_{i}$ are external instruments.

The assumption $E\left(z_{i} u_{i}\right)=0$ implies that $\beta$ solves the system of $r$ equations:

$$
E\left[z_{i}\left(y_{i}-x_{i}^{\prime} \beta\right)\right]=0
$$

or

$$
\begin{equation*}
E\left(z_{i} x_{i}^{\prime}\right) \beta=E\left(z_{i} y_{i}\right) \tag{6}
\end{equation*}
$$

If $r<k$, system (6) will have a multiplicity of solutions for $\beta$, so that $\beta$ is not point identified. If $r \geq k$ and $\operatorname{rank} E\left(z_{i} x_{i}^{\prime}\right)=k$ then $\beta$ is identified. In estimation we will distinguish between the just-identified case ( $r=k$ ) and the over-identified case ( $r>k$ ).

If $r=k$ and the rank condition holds we have

$$
\begin{equation*}
\beta=\left[E\left(z_{i} x_{i}^{\prime}\right)\right]^{-1} E\left(z_{i} y_{i}\right) \tag{7}
\end{equation*}
$$

In the simple case where $x_{i}=\left(1, x_{o i}\right)^{\prime}, z_{i}=\left(1, z_{o i}\right)^{\prime}$ and $\beta=\left(\beta_{1}, \beta_{2}\right)^{\prime}$ we get

$$
\beta_{2}=\frac{\operatorname{Cov}\left(z_{o i}, y_{i}\right)}{\operatorname{Cov}\left(z_{o i}, x_{o i}\right)}
$$

and

$$
\beta_{1}=E\left(y_{i}\right)-\beta_{2} E\left(x_{o i}\right) .
$$

In general, the OLS parameters will differ from the parameters in the instrumental-variable model. In the previous simple example we have:

$$
\begin{equation*}
\frac{\operatorname{Cov}\left(x_{i}, y_{i}\right)}{\operatorname{Var}\left(x_{i}\right)}=\beta_{2}+\frac{\operatorname{Cov}\left(x_{i}, u_{i}\right)}{\operatorname{Var}\left(x_{i}\right)} . \tag{8}
\end{equation*}
$$

Sometimes the orthogonality between instruments and error term is expressed in the form of a stronger mean independence assumption instead of lack of correlation:

$$
E\left(u_{i} \mid z_{i}\right)=0
$$

### 3.2 Examples

Demand equation In this example the units are markets across space or over time, $y_{i}$ is quantity, the endogenous explanatory variable is price and the external instrument is a supply shifter, such as weather variation in the case of an agricultural product. This is the classic example from the simultaneous equations literature. ${ }^{1}$

Evaluation of a training program Here the units are workers, the endogenous explanatory variable is an indicator of participation in a training program and $y_{i}$ is some subsequent labor market outcome, such as wages or employment status. The external instrument is an indicator of random assignment to access to the program. In this example we would expect the coefficient in the instrumental-variable line to be positive, whereas the coefficient in the OLS line could be negative.

Measurement error Consider the measurement error regression model:

$$
y_{i}=\beta_{1}+\beta_{2} x_{i}^{*}+v_{i}
$$

where we observe two measurements of $x_{i}^{*}$ with independent errors:

$$
\begin{aligned}
& x_{1 i}=x_{i}^{*}+\varepsilon_{1 i} \\
& x_{2 i}=x_{i}^{*}+\varepsilon_{2 i} .
\end{aligned}
$$

All unobservables $\left\{x_{i}^{*}, v_{i}, \varepsilon_{1 i}, \varepsilon_{2 i}\right\}$ are mutually independent. In this example, we could have $x_{i}=$ $\left(1, x_{1 i}\right)^{\prime}, z_{i}=\left(1, x_{2 i}\right)^{\prime}$ and $u_{i}=v_{i}-\beta_{2} \varepsilon_{1 i}$; or alternatively $x_{i}=\left(1, x_{2 i}\right)^{\prime}, z_{i}=\left(1, x_{1 i}\right)^{\prime}$ and $u_{i}=v_{i}-\beta_{2} \varepsilon_{2 i}$.

Time series regression with dynamics and serial correlation A simple example is the ARMA $(1,1)$ model:

$$
\begin{aligned}
& y_{t}=\beta_{1}+\beta_{2} y_{t-1}+u_{t} \\
& u_{t}=\varepsilon_{t}+\theta \varepsilon_{t-1}
\end{aligned}
$$

where $\varepsilon_{t}$ is a white noise error term. Here $x_{t}=\left(1, y_{t-1}\right)^{\prime}$ and $z_{t}=\left(1, y_{t-2}\right)^{\prime}$.

### 3.3 Estimation

Simple IV estimator When $r=k$ a simple instrumental-variable estimator is the sample counterpart of (7):

$$
\widehat{\beta}=\left(\sum_{i=1}^{n} z_{i} x_{i}^{\prime}\right)^{-1} \sum_{i=1}^{n} z_{i} y_{i} .
$$

[^0]The estimation error is given by

$$
\widehat{\beta}-\beta=\left(\frac{1}{n} \sum_{i=1}^{n} z_{i} x_{i}^{\prime}\right)^{-1} \frac{1}{n} \sum_{i=1}^{n} z_{i} u_{i} .
$$

Thus, $\operatorname{plim}_{n \rightarrow \infty} \widehat{\beta}=\beta$ if $\operatorname{plim} \frac{1}{n} \sum_{i=1}^{n} z_{i} x_{i}^{\prime}=E\left(z_{i} x_{i}^{\prime}\right)=H$, rank $H=k$, and $\operatorname{plim} \frac{1}{n} \sum_{i=1}^{n} z_{i} u_{i}=$ $E\left(z_{i} u_{i}\right)=0$.

Also,

$$
\sqrt{n}(\widehat{\beta}-\beta) \xrightarrow{d} \mathcal{N}\left(0, H^{-1} W H^{\prime-1}\right)
$$

if $n^{-1 / 2} \sum_{i=1}^{n} z_{i} u_{i} \xrightarrow{d} \mathcal{N}(0, W)$. When $\left\{y_{i}, x_{i}, z_{i}\right\}_{i=1}^{n}$ is a random sample then $W=E\left(u_{i}^{2} z_{i} z_{i}^{\prime}\right)$.

Overidentified IV If $r>k$ the system (6) contains more equations than unknowns. To determine the population value of $\beta$ we could solve any rank-preserving $k$ linear combinations for some $k \times r$ matrix $G$ :

$$
G E\left(z_{i} x_{i}^{\prime}\right) \beta=G E\left(z_{i} y_{i}\right)
$$

so that

$$
\begin{equation*}
\beta=\left[E\left(G z_{i} x_{i}^{\prime}\right)\right]^{-1} E\left(G z_{i} y_{i}\right), \tag{9}
\end{equation*}
$$

leading to consistent estimators of the form

$$
\begin{equation*}
\widehat{\beta}_{G}=\left(\sum_{i=1}^{n} G z_{i} x_{i}^{\prime}\right)^{-1} \sum_{i=1}^{n} G z_{i} y_{i} . \tag{10}
\end{equation*}
$$

Note that while (9) should be invariant to the choice of $G$ if the model is correctly specified, the estimated quantity (10) will differ due to sample error. For example, if $x_{i}=\left(1, x_{o i}\right)^{\prime}$ and $z_{i}=$ $\left(1, z_{1 i}, z_{2 i}\right)^{\prime}$ we will have

$$
\frac{\operatorname{Cov}\left(z_{1 i}, y_{i}\right)}{\operatorname{Cov}\left(z_{1 i}, x_{o i}\right)}=\frac{\operatorname{Cov}\left(z_{2 i}, y_{i}\right)}{\operatorname{Cov}\left(z_{2 i}, x_{o i}\right)}
$$

but

$$
\frac{\widehat{\operatorname{Cov}}\left(z_{1 i}, y_{i}\right)}{\widehat{\operatorname{Cov}}\left(z_{1 i}, x_{o i}\right)} \neq \frac{\widehat{\operatorname{Cov}}\left(z_{2 i}, y_{i}\right)}{\widehat{\operatorname{Cov}}\left(z_{2 i}, x_{o i}\right)} .
$$

Asymptotic normality Turning to large sample properties, repeating the previous asymptotic normality argument for (10), under iid sampling we get:

$$
\sqrt{n}\left(\widehat{\beta}_{G}-\beta\right) \xrightarrow{d} \mathcal{N}\left(0, V_{G}\right)
$$

with

$$
\begin{equation*}
V_{G}=\left[G E\left(z_{i} x_{i}^{\prime}\right)\right]^{-1} G E\left(u_{i}^{2} z_{i} z_{i}^{\prime}\right) G^{\prime}\left[E\left(x_{i} z_{i}^{\prime}\right) G^{\prime}\right]^{-1} . \tag{11}
\end{equation*}
$$

Thus, the large sample variance depends on the choice of $G$.

Optimality Let us now consider optimality following Sargan (1958). ${ }^{2}$ For $G=E\left(x_{i} z_{i}^{\prime}\right)\left[E\left(u_{i}^{2} z_{i} z_{i}^{\prime}\right)\right]^{-1}$ the matrix $V_{G}$ equals

$$
V_{0}=\left[E\left(x_{i} z_{i}^{\prime}\right)\left[E\left(u_{i}^{2} z_{i} z_{i}^{\prime}\right)\right]^{-1} E\left(z_{i} x_{i}^{\prime}\right)\right]^{-1} .
$$

Moreover, it can be shown that for any other choice of $G$ we have: ${ }^{3}$

$$
V_{G}-V_{0} \geq 0
$$

Therefore, estimators of the form

$$
\begin{equation*}
\widehat{\beta}_{G_{n}}=\left(\sum_{i=1}^{n} G_{n} z_{i} x_{i}^{\prime}\right)^{-1} \sum_{i=1}^{n} G_{n} z_{i} y_{i} \tag{12}
\end{equation*}
$$

with a possibly stochastic $G_{n}$ such that $G_{n} \xrightarrow{p} E\left(x_{i} z_{i}^{\prime}\right)\left[E\left(u_{i}^{2} z_{i} z_{i}^{\prime}\right)\right]^{-1}$ (up to a multiplicative constant) are optimal in the sense of being minimum asymptotic variance within the class of linear instrumentalvariable estimators, which use $z_{i}$ as instruments.

Under homoskedasticity $E\left(u_{i}^{2} z_{i} z_{i}^{\prime}\right)=\sigma^{2} E\left(z_{i} z_{i}^{\prime}\right)$, therefore a choice of $G_{n}$ such that

$$
G_{n} \xrightarrow{p} E\left(x_{i} z_{i}^{\prime}\right)\left[E\left(z_{i} z_{i}^{\prime}\right)\right]^{-1}=\Pi
$$

is optimal. The matrix $\Pi$ contains the OLS population coefficients in linear regressions of the $x_{i}$ variables on $z_{i}$.

Two-stage least squares Letting $\widehat{\Pi}=\left(\sum_{i=1}^{n} x_{i} z_{i}^{\prime}\right)\left(\sum_{i=1}^{n} z_{i} z_{i}^{\prime}\right)^{-1}$ be the sample counterpart of $\Pi$, the two-stage least squares estimator is

$$
\begin{equation*}
\widehat{\beta}_{2 S L S}=\left(\sum_{i=1}^{n} \widehat{\Pi} z_{i} x_{i}^{\prime}\right)^{-1} \sum_{i=1}^{n} \widehat{\Pi} z_{i} y_{i} \tag{13}
\end{equation*}
$$

or in short

$$
\begin{equation*}
\widehat{\beta}_{2 S L S}=\left(\sum_{i=1}^{n} \widehat{x}_{i} x_{i}^{\prime}\right)^{-1} \sum_{i=1}^{n} \widehat{x}_{i} y_{i} \tag{14}
\end{equation*}
$$

where $\widehat{x} i=\widehat{\Pi} z_{i}$ is the vector of fitted values in the ("first-stage") regressions of the $x_{i}$ variables on $z_{i}$ :

$$
\begin{equation*}
x_{i}=\Pi z_{i}+v_{i} \tag{15}
\end{equation*}
$$

[^1]If a variable in $x_{i}$ is also contained in $z_{i}$ its fitted value will coincide with the variable itself and the corresponding element of $v_{i}$ will be equal to zero.

Sometimes it is convenient to use matrix notation as follows:

$$
\widehat{\Pi}=\left(X^{\prime} Z\right)\left(Z^{\prime} Z\right)^{-1}
$$

so that

$$
\widehat{\beta}_{2 S L S}=\left[\left(X^{\prime} Z\right)\left(Z^{\prime} Z\right)^{-1}\left(Z^{\prime} X\right)\right]^{-1}\left(X^{\prime} Z\right)\left(Z^{\prime} Z\right)^{-1}\left(Z^{\prime} y\right)
$$

and

$$
\widehat{\beta}_{2 S L S}=\left(\widehat{X}^{\prime} X\right)^{-1} \widehat{X}^{\prime} y
$$

where $\widehat{X}=Z\left(Z^{\prime} Z\right)^{-1}\left(Z^{\prime} X\right)$.
Note that $\widehat{\beta}_{2 S L S}$ is also the OLS regression of $y$ on $\widehat{X}$ :

$$
\widehat{\beta}_{2 S L S}=\left(\widehat{X}^{\prime} \widehat{X}\right)^{-1} \widehat{X}^{\prime} y .
$$

This interpretation of the 2SLS estimator is the one that originated its traditional name.
Two-stage least squares estimation relies on a powerful intuition: we use as instrument the linear combination of the instrumental variables that best predicts the endogenous explanatory variables in the linear projection sense.

Consistency of $\widehat{\beta}_{2 S L S}$ relies on $n \rightarrow \infty$ for fixed $r$. Note that if $r=n$ then $\widehat{X}=X$ so that 2SLS and OLS coincide. If $r$ is less than $n$ but close to it, one would expect 2SLS to be close to OLS.

Robust standard errors Although its optimality requires homoskedasticity, 2SLS (like OLS) remains a popular estimator under more general conditions. Particularizing expression (11) to $G=\Pi$ we obtain the asymptotic variance of the 2SLS estimator

$$
\begin{equation*}
V_{\Pi}=\left[\Pi E\left(z_{i} z_{i}^{\prime}\right) \Pi^{\prime}\right]^{-1} \Pi E\left(u_{i}^{2} z_{i} z_{i}^{\prime}\right) \Pi^{\prime}\left[\Pi E\left(z_{i} z_{i}^{\prime}\right) \Pi^{\prime}\right]^{-1} . \tag{16}
\end{equation*}
$$

Heteroskedasticity-robust standard errors and confidence intervals can be obtained from the estimated variance:

$$
\begin{aligned}
\widehat{V}_{\Pi} & =\left[\widehat{\Pi} \widehat{E}\left(z_{i} z_{i}^{\prime}\right) \widehat{\Pi}^{\prime}\right]^{-1} \widehat{\Pi} \widehat{E}\left(\widehat{u}_{i}^{2} z_{i} z_{i}^{\prime}\right) \widehat{\Pi}^{\prime}\left[\widehat{\Pi} \widehat{E}\left(z_{i} z_{i}^{\prime}\right) \widehat{\Pi}^{\prime}\right]^{-1} \\
& =n\left(\widehat{X}^{\prime} \widehat{X}\right)^{-1}\left(\sum_{i=1}^{n} \widehat{u}_{i}^{2} \widehat{x}_{i} \widehat{x}_{i}^{\prime}\right)\left(\widehat{X}^{\prime} \widehat{X}\right)^{-1}
\end{aligned}
$$

where the $\widehat{u}_{i}$ are 2SLS residuals $\widehat{u}_{i}=y_{i}-x_{i}^{\prime} \widehat{\beta}_{2 S L S}$.
With homoskedastic errors, (16) boils down to

$$
\begin{equation*}
V_{\Pi}=\sigma^{2}\left[\Pi E\left(z_{i} z_{i}^{\prime}\right) \Pi^{\prime}\right]^{-1} \tag{17}
\end{equation*}
$$

where $\sigma^{2}=E\left(u_{i}^{2}\right)$. In this case a consistent estimator of $V_{\Pi}$ is simply

$$
\begin{equation*}
\widetilde{V}_{\Pi}=n \widehat{\sigma}^{2}\left(\widehat{X}^{\prime} \widehat{X}\right)^{-1} \tag{18}
\end{equation*}
$$

where $\widehat{\sigma}^{2}=n^{-1} \sum_{i=1}^{n} \widehat{u}_{i}^{2}$.
Note that if the residual variance is calculated from fitted-value residuals $y-\widehat{X} \widehat{\beta}_{2 S L S}$ instead of $\widehat{u}=y-X \widehat{\beta}_{2 S L S}$, we would get an inconsistent estimate of $\sigma^{2}$ and therefore also of $V_{\Pi}$ in (17).

### 3.4 Testing overidentifying restrictions

When $r>k$ an IV estimator sets to zero $k$ linear combinations of the moments:

$$
G E\left(z_{i} x_{i}^{\prime}\right) \beta=G E\left(z_{i} y_{i}\right)
$$

Thus, there remains $r-k$ linearly independent combinations that are not set to zero in estimation but should be close to zero under correct specification. A test of overidentifying restrictions or Sargan test is a test of the null hypothesis that the remaining $r-k$ linear combinations are equal to zero.

Under classical errors the form of the statistic is given by

$$
\begin{equation*}
S=\frac{\widehat{u}^{\prime} Z\left(Z^{\prime} Z\right)^{-1} Z^{\prime} \widehat{u}}{\widehat{\sigma}^{2}} \xrightarrow{d} \chi_{r-k}^{2} \tag{19}
\end{equation*}
$$

It is easy to see that $S=n R^{2}$ where $R^{2}$ is the r-squared in a regression of $\widehat{u}$ on $Z$.
A sketch of the result in (19) is as follows. With classical errors $n^{-1 / 2} \sum_{i=1}^{n} z_{i} u_{i} \xrightarrow{d} \mathcal{N}\left[0, \sigma^{2} E\left(z_{i} z_{i}^{\prime}\right)\right]$ and therefore also

$$
\frac{1}{\sqrt{n}} \frac{1}{\hat{\sigma}} C^{\prime} Z^{\prime} u \xrightarrow{d} \mathcal{N}\left(0, I_{r}\right)
$$

where we are using the factorization $\left(Z^{\prime} Z / n\right)^{-1}=C C^{\prime}$.
Next, using

$$
\widehat{u}=y-X \widehat{\beta}_{2 S L S}=u-X\left(\widehat{\beta}_{2 S L S}-\beta\right)
$$

and

$$
\widehat{\beta}_{2 S L S}-\beta=\left[\left(X^{\prime} Z\right)\left(Z^{\prime} Z\right)^{-1}\left(Z^{\prime} X\right)\right]^{-1}\left(X^{\prime} Z\right)\left(Z^{\prime} Z\right)^{-1} Z^{\prime} u
$$

we get

$$
h=\frac{1}{\sqrt{n}} \frac{1}{\hat{\sigma}} C^{\prime} Z^{\prime} \widehat{u}=\left[I_{r}-B\left(B^{\prime} B\right)^{-1} B^{\prime}\right] \frac{1}{\sqrt{n}} \frac{1}{\hat{\sigma}} C^{\prime} Z^{\prime} u
$$

where $B=C^{\prime}\left(Z^{\prime} X / n\right)$.
Since the probability limit of $\left[I-B\left(B^{\prime} B\right)^{-1} B^{\prime}\right]$ is idempotent with rank $r-k$ it follows that

$$
h^{\prime} h=n \frac{\widehat{u}^{\prime} Z\left(Z^{\prime} Z\right)^{-1} Z^{\prime} \widehat{u}}{\widehat{u}^{\prime} \widehat{u}} \xrightarrow{d} \chi_{r-k}^{2} .
$$

In the presence of heteroskedasticity, the statistic $S$ in (19) is not asymptotically chi-square, not even under correct specification. An alternative robust Sargan statistic is:

$$
\begin{equation*}
S_{R}=\left(\widetilde{u}^{\prime} Z\right) \widetilde{W}^{-1}\left(Z^{\prime} \widetilde{u}\right) \xrightarrow{d} \chi_{r-k}^{2} \tag{20}
\end{equation*}
$$

where $\widetilde{W}=\left(\sum_{i=1}^{n} \widehat{u}_{i}^{2} z_{i} z_{i}^{\prime}\right)$ and $\widetilde{u}=y-X \widehat{\beta}_{G_{n}^{\dagger}}$ with $G_{n}^{\dagger}=\left(X^{\prime} Z\right) \widetilde{W}^{-1}$.
Contrary to $\widehat{\beta}_{2 S L S}$, the IV estimator $\widehat{\beta}_{G_{n}^{\dagger}}$ given by

$$
\begin{equation*}
\widehat{\beta}_{G_{n}^{\dagger}}=\left[\left(X^{\prime} Z\right) \widetilde{W}^{-1}\left(Z^{\prime} X\right)\right]^{-1}\left(X^{\prime} Z\right) \widetilde{W}^{-1}\left(Z^{\prime} y\right) \tag{21}
\end{equation*}
$$

uses an optimal choice of $G_{n}$ under heteroskedasticity. This improved IV estimator was studied by Halbert White in 1982 under the name two-stage instrumental variables (2SIV) estimator. ${ }^{4}$

[^1]:    ${ }^{2}$ Sargan, J. D. (1958): "The Estimation of Economic Relationships Using Instrumental Variables," Econometrica, 26, 393-415.
    ${ }^{3}$ To see this, let $W^{-1}=C^{\prime} C, \bar{H}=C H, \bar{D}=(G H)^{-1} G C^{-1}$, and note that:

    $$
    V_{G}-V_{0}=(G H)^{-1} G W G^{\prime}\left(H^{\prime} G^{\prime}\right)^{-1}-\left(H^{\prime} W^{-1} H\right)^{-1}=\bar{D}\left[I-\bar{H}\left(\bar{H}^{\prime} \bar{H}\right)^{-1} \bar{H}^{\prime}\right] \bar{D}^{\prime} .
    $$

    This is a positive semi-definite matrix because $\left[I-\bar{H}\left(\bar{H}^{\prime} \bar{H}\right)^{-1} \bar{H}^{\prime}\right]$ is idempotent. This optimality result also applies to clustered and serially dependent data since it does not require that $W$ equals $E\left(u_{i}^{2} z_{i} z_{i}^{\prime}\right)$.
